Abstract

Accurate quantification of intron retention levels is currently the crux for detecting and interpreting the function of retained introns. Using both simulated and real RNA-seq datasets, we show that current methods suffer from several biases and artefacts, which impair the analysis of intron retention. We designed a new approach to measuring intron retention levels called the Stable Intron Retention ratio that we have implemented in a novel algorithm to detect and measure intron retention called S-IRFindeR. We demonstrate that it provides a significant improvement in accuracy, higher consistency between replicates and agreement with IR-levels computed from long-read sequencing data.

S-IRFindeR is freely available at: https://github.com/lbroseus/SIRFindeR/.

Keywords

Intron Retention, Splicing Efficiency, RNA-sequencing

Background

Intron Retention (IR) is a type of alternative splicing that is gaining increased interest in human health and disease research. Originally described in plants and viruses, IR has now been shown to be a common form of alternative splicing in mammalian systems [1]. However, quantifying IR levels poses several specific difficulties [1–3]. Introns are highly heterogeneous genomic regions, both in length and sequence features. In mammals, IR levels are generally low and thereby subject to incomplete coverage and higher count overdispersion [4,5].

Two approaches have been proposed to address the specifics of IR-level quantitation [3]: an intronic-tuned version of the Percentage Spliced-In (PSI) value [6,7], and our own IRratio [1] **(Table 1**). Both methods estimate the portion of transcripts including the intron (*intronic abundance*) and the portion of spliced transcripts (*splicing abundance*), and compute the retention fraction as the ratio: intronic abundance / (splicing abundance + intronic abundance), but they differ markedly in their strategy to measure these two quantities (cf: [3] for a review).

Though these methods have been recently used to quantify IR events in a wide range of studies [8–15], their capacity to actually reflect true IR transcripts has not undergone any validation yet [2,16]. In fact, several authors including ourselves highlight the high-variability and lack of reproducibility of IR level estimates [2,17].

Table 1 : Existing measures to estimate IR levels from short RNA-seq data and their implementation.

IR measure	**Software**	**Language**	**Year**
PSI	KMA	Python/R	2015
IRratio	IRFinder	C++	2017
SIRratio	S-IRFindeR	R	2020

Results and Discussion

By analysing both simulated and real data (Supplementary Methods), we found that current estimators frequently report aberrant IR values. Many of these are known to be caused by splicing events that are absent from reference annotations [3] (especially novel 3' or 5' donor sites). In addition, we found that the IRratio and PSI calculated by KMA provided poor estimates of normal splicing and intronic abundance and produced aberrant zero and one values which led to inconsistent IR levels (**Figure 1A** and **Supplementary Figure 1 and 2**). These extreme values of "1" and "0" are a major handicap for downstream analyses. An artifactual value of 1 can be falsely interpreted as "all transcripts retain this intron" and will thus be considered as prime candidates for further bioinformatics analysis or even experimental validation. A false value of 0 will constitute a false negative but in addition will perturb differential IR analysis between conditions. We also found that both the IRratio and PSI had a tendency to underestimate the level of the longest introns (**Figure 1B**).

Taking into consideration these biases, we shaped a novel estimator, coined SIRratio for Stable Intron Retention ratio. We used a shrinkage approach to share coverage information at the gene level and improve the stability and interpretability of normal splicing estimates. We integrated this novel metric into a new version of IRFinder that we called S-IRFinder. To assess the efficiency of the SIRatio, we first generated multiple sets of simulated IR events with varying coverage and retention levels (**Supplementary Materials**). We found that the IR levels found by the SIRatio were closer to the real levels (**Figure 1C and Supplementary Figure 2**). We then used real mRNA sequencing data and measured the distances between technical replicates of the same condition. We found that the SIRatio was more consistent between replicates (**Figure 1D, Supplementary Figures 3 & 4**) than the IRratio or the PSI.

Third-generation sequencing technologies and more specifically direct RNA sequencing, developed by Oxford Nanopore Technologies, represent a unique opportunity for the detection, characterization and validation of IR. Because these technologies are capable of sequencing RNA molecules from start to end, they can elucidate the full structure of transcripts with retained introns. In S-IRFinder, we implemented the capability to use long-read sequencing technologies to detect and measure IR (Supplementary Materials).

Conclusion

Until recently, IR detection ran parallel with the analysis of other splicing events without taking into account inherent difficulties in measuring intronic expression. As a result, IR had been systematically underestimated. Despite the recent development of specialized software for detecting IR, the measurement of IR levels has been problematic. Poor estimates of IR levels may distort the downstream analysis of enriched gene families, confound differential analysis of IR between biological conditions and lead to erroneous conclusions about the impact of IR in normal biology and disease. We developed a new metric, the SIRratio that stabilizes the estimates of IR by using a localized shrinkage approach and a more accurate definition of intronic regions. This approach gives more accurate IR estimates when compared with simulated IR transcripts but also with third-generation long-read technology. It also gives more stable IR estimates between technical replicates. The SIRratio is now implemented in S-IRFindeR that we recommend as an alternative to our own IRFinder algorithm.

Methods

Building on IRFinder's approach [1,3] and taking into account several biases which can adversely affect current IR measures, we devised a new approach for quantifying IR-levels, called S-IRFindeR.

Data-driven refinement of intron annotation. Default in intron annotation is a major cause for inaccurate IR values [16]. Current methods address this issue by detecting spurious coverage patterns (eg: read coverage entropy [18], probabilistic test [6]) that may impair quantitation, and exclude affected introns from downstream analyses. To allow considering even introns with unexpected alternative splicing events, we propose instead a procedure to polish intron intervals using sample-specific junctions (cf: **Supplementary Materials**).

Stabilized estimation of IR-levels. Observing that splice junction counts and the median intron depth could provide unstable measures of the abundances of spliced and IR transcripts respectively, we stepped on popular shrinkage [19,20] and resampling techniques [21] to

formulate a novel metric, the SIRratio (cf: **Supplementary Materials**).

Benchmark. To evaluate the ability of the three IR-measures to reflect the true proportion of IR-transcripts, we generated 45 RNA-seq samples with known IR-levels, alternative exon splicing and varying gene coverage (**cf: Supplementary Materials**).

We then sought to extend our study to real RNA-seq data. Assuming IR-levels should be similar across technical replicates, we made use of five RNA-seq Poly-A runs, with varying library size, available from the human cell line GM12878 [22] to evaluate the capacity of each method to provide reproducible results. In order to evaluate reproducibility, we computed the distances between technical replicates [23] (**cf: Figure 1C, Supplementary Figure 3 and Supplementary Table 2**) in addition to correlation coefficients (**cf: Supplementary Figure 4**). What also motivated the choice for this RNA-seq experiment, was the availability of a deep long read experiment (over 10 million long reads) from the same cell line [24]. As a means to validate short read estimates on real data, we compared them to those computed from long-read data (**cf: Figure 1D and Supplementary Table 3**).
